ABSTRACT: The present paper describes the path walked by the Environmental Agency of Rio de Janeiro (INEA) towards the implementation of a reliable weather forecast system in order to prevent impacts due to extreme events. In 2007 INEA started to acquire new equipment, extending its data collection net and aiming to create a flash flood warning system, through monitoring rain and river levels. It was a huge gain, but the system was only able to anticipate the events a few minutes before it happened, thus the agency decided to increment the forecast system with more robust equipment. In 2012 it started the proceedings to install weather radars. Nowadays, the net operated by INEA encompass 2 S-Band weather radars, installed at the cities of Rio de Janeiro and Macaé, capable of quantifying water in the atmosphere up to 250 km radius, which makes the State of Rio de Janeiro the first one in Brazil to have all its catchments covered by radar technology, including the neighbor States areas, besides 130 water levels and rain monitoring stations. This net provides data to the technical personnel, which interpret the collected information and contact the response teams in the municipal, state and federal levels, in case of need. Taking Quitandinha basin as an example, the mean lead time has significantly increased since the operation of the radar system. It was about 3 hours from 2011 to 2014 and increased to more than 6 hours during the last rainy season.

Keywords Warning system, flash flood, weather radar

1. INTRODUCTION

The State of Rio de Janeiro since long time has equipment measuring the quality of the water in a few specific spots, as the Guanabara Bay (where the data goes back 30 years). Besides these measurement spots there were a few others which collected information with regards to water levels, intended to provide data to water collection systems.

Those hydrometeorological stations were of conventional reading at first, but after 2000 some stations, especially those installed at Rio de Janeiro lowland area, were automatized and gained telemetric data transmission.

Due to extreme weather events, the environmental agency decided to extend such data collection net in order to create a system that would anticipate heavy rains and its consequences. That system would allow the authorities to inform the potentially affected areas and prevent the loss of lives and properties.

1.1 The beginning of Rio de Janeiro's Flash Flood Warning System

In 2007 the agency started to acquire new equipment to lively monitor the rain and water levels of rivers which were relevant to its drainage basin. In order words, considering limited resources, the agency chose to install the measurement stations in the most important water bodies.

Rio de Janeiro lowland area received the first warning system of the state in 2008, when INEA started using a few telemetric stations that were installed before. During the same year new telemetric stations were installed in Nova Friburgo, a municipality in the mountain area, which gave rise to the second warning system in the state. Later, in 2011, the monitoring spread to the north area of the state, where flood events are not so frequent, but affect large areas for many days.

Unfortunately, during that same year Brazil faced its greatest natural disaster, when large accumulated precipitation reached the mountainous region of Rio de Janeiro for several consecutive days, causing associated events of landslides and floods, taking hundreds of lives. After that, INEA inherited a weather station network from a research centre located in Petropolis, one of the most affected municipalities.

1.2 Rio de Janeiro's Weather Radars

The hydrometeorological stations were only able to anticipate an extreme event a few minutes before it happened. This means that, only after the water levels were significantly above the regular standards, it was possible for the Civil Defences to make the decision about an evacuation or other protection measures.

In this sense, the agency decided to increment the forecast system with more robust equipment. In 2012 it started the proceeding to install weather radars. The challenges to such idea were enormous and the doubts were vast: (i) What equipment to acquire? (ii) Should an environmental agency be responsible for weather forecast? (iii) Where would such expensive and complex equipment be installed? (iv) Which allocation could provide maximum coverage with minimum risks; (v) How would the agency operate and maintain such radars? Among several others.

The acquisition of the radars were only initiate after answering the aforementioned questions and the entire process took more than one year, considering the public tender proceedings, equipment and building erection, personnel training and actual operation of the facilities. All of this was funded by the World Bank.

1.3 Network new challenges

When a network becomes big, new challenges are faced. The first one is that it requires people enough to analyse the data, 24 hours a day, 7 days a week. In 2008 INEA entered into a contract in order to operate the System, however this contract only provided 3 meteorologists and 4 meteorology technicians, which allowed only 1 person each shift to monitor the entire state. When that contract was over, in 2015, a new one was signed and had 1 meteorologist coordinator, 3 meteorologists in shifts, 5 meteorology technicians in shifts, and 1 more meteorology technician working on business hours to maintain contact with 5 field maintenance technicians. That number of professionals allows 2 people each shift to analyse the data, operate the radars, send alerts and make reports.

It is now much better than before, but is still a challenge since the team has to evaluate each type of data separately (weather and hydrological stations, weather radars, lightning, satellite images). Thus, the team is evaluating softwares capable of integrate several types of data and make new products through them. There are some shelf solutions at the market and the one to be chosen shall be able to integrate other environmental data such as air quality and water quality and forest fire risk.

It is notable that the System's efficiency has increased, but we need a way to quantify such evolution, as part of INEA's compromise to the World Bank.

2. MATERIALS AND METHODS

2.1 Flash flood alert system network

Currently there are 108 water levels monitoring stations (most of them with rain sensor too) and 42 rain monitoring stations (figure 1). This net provides data to the technical personnel, that interprets the collected information and contact the response teams in the municipal, state and federal levels, in case of need.

In addition to that, the net operated by the Environmental Agency of the State of Rio de Janeiro encompasses 2 S-Band weather radars, installed at the cities of Rio de Janeiro and Macaé, capable of quantifying water in the atmosphere up to 250 km radius, which makes the State of Rio de Janeiro the first in Brazil to have all its catchments covered by radar technology, including the neighbour States' areas.

Both the radars operations and data forwarding system work remotely, using a dedicated internet link between the radar sites and INEA. After receiving these data, INEA sends predetermined products to some clients, as Rio de Janeiro City Alert System (that sends heavy rain and landslides alerts), the North of Rio de Janeiro State University (research in meteorology), among other partners. All of it is possible because the data provided by the radars allow multiple kinds of use, therefore Rio de Janeiro's government encourages data sharing, especially for the prevention of natural disasters.

2.2 Flash flood alert system protocol

The flash flood watch system works following three steps. The protocol is descripted in figure 2.

- 1) The flash flood alert system has a network of telemetric stations and weather radars that send data in real time, regarding rain and river level.
- 2) In the situation room, meteorologists and meteorology technicians monitor the weather and river levels 24 hours a day, every day.
- 3) When there is heavy rain or overflow forecast, INEA sends alerts via SMS to civil defence agents and registered population.

| Stage | Situation |
|------------------|---|
| Vigilance | No significant rain forecast that could cause rivers level elevation. |
| Attention | River level elevation is possible because of rain occurrence. |
| Alert | Elevation above normal level of a monitored river, with elevation forecast. |
| Maximum alert | Imminent overflow of a monitored river, with elevation forecast. |
| Overflow | Overflow of a monitored river registered. |

Figure 2. Flash flood alert system protocol. Source: INEA, 2016

Every alert emitted is registered at a spread sheet, which contains the time when it happened, the watershed, municipality, station, river and the warning level sent, like the example of figure 3.

2.3 Contingency table method

One of the big issues we wanted to minimize is the false alarm rate, therefore we have used the contingency table method (table 1) in order to quantify some statistic indexes and assess the system accuracy (Murphy, 1993). The numbers of alerts sent in the past 4 years are show in table 2.

| | Table 1. Contingency table | | | | | | |
|------------|----------------------------|-------|-------|----------------------|--|--|--|
| | Event Observed | | | | | | |
| | | Yes | No | Total | | | |
| Event | Yes | А | В | A + B | | | |
| Forecasted | No | С | D | C + D | | | |
| | Total | A + C | B + D | A + B + C + D = N | | | |

Where: A = Hits; B = False alarms; C = Misses; D = Correct negatives

| Table 2. Total number of alerts sent | | | | | | | | |
|--------------------------------------|-------------|--------------|--------------|-----------|-------|--------------|----------|--|

| 30 | 0 | 2 | 1 | 14 | 0 | 0 | 0 | |

2.4 Lead Time

Another point likely to improve with the use of radars is the lead time on sending alerts. Cel. Veiga station, located in Quitandinha river basin, was selected considering it is the one for which the greatest number of alerts is emitted.

We could not expect a great lead time for this station considering the small size of its contribution area (13 Km²), in a downhill area. In this sense a hydrograph analysis was used to quantify some parameters, such as its response time, using LENCASTRE & FRANCO's (1984) proposal described in figure 4.

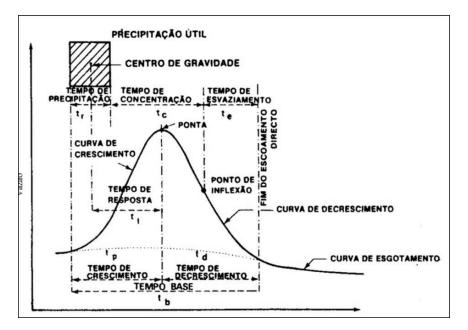

Figure 4.Hydrograph analysis model. Source: LENCASTRE & FRANCO, 1984

After that, all of the alert protocol to Cel. Veiga's station were listed and separated, taking into account two periods: (i) between the date of its installation to 2015's dry season; and (ii) 2015-2016's rain season. All the processes are listed in table 3.

3. RESULTS AND DISCUSSION

3.1 False Alarm Rate

In accordance with the methodology adopted herein, a false alarm happens when, after issuing a maximum alert, an overflow event does not occur. A false alarm situation can happen for multiple factors, including the decrease of the rain, inaccuracy of the data and lack of information with regards to the basin contribution area and runoff characteristics.

As can be seen by the figure 5, the false alarm rate was calculated for the last 4 years considering the progress between all the steps and the values such as displayed below.

SBE16 Brazil&Portugal Sustainable Urban Communities towards a Nearly Zero Impact Built Environment ISBN: 978-85-92631-00-0

The figure above shows that there is still room for improvement in the State's forecast system, despite the recent expansion of the net. In this sense, it is important to note that the acquisition of new and more modern equipment were steps needed to be taken in the past.

Nowadays, however, it is important to provide new products from the data collected by the radars and monitoring stations. In others words, although the equipment may be able to provide a significant amount of raw data, the agency should be able to extract more information by means of more sophisticated interpretation proceedings.

In this sense, information such as contribution area and runoff coefficients, for example, can help to improve the forecast interpretation methodology as well as the system's accuracy. The knowledge of whole characteristics of the watershed is the main factor to decrease the number of false alarms.

In addition to that, we also need to be able to interpret and cross exam different types of data, such as weather conditions, water levels and basin characteristics, for example.

3.2 Lead Time to Quitandinha

In order to estimate some hydrological parameters using the hydrograph method, we have analysed the most important overflow cases for Cel. Veiga station during the last rain season. Table 4 give us all hydrological parameters estimated for this station and Figure 6 shows an example of the analysis.

After assessing the results from table 4, it is clear that Quitandinha basin has a small response time (1h) and is vulnerable to overflows during events with moderate rain amounts (~ 20 mm/h). The growth line is very steep (figure 6) and it takes just 1 hour to change between a normal to an overflow level. It happens because of the small size of the basin and the slope geography of the area.

Taking this into account, we have compared the time between Petrópolis city receiving an attention warning and the overflow of Quitandinha's river. The results are shown in tables 5 and 6 and are separated in accordance with the periods before and after the radar system implementation.

Comparing the average lead time before and after the radar system operation, it has grown from \sim 3h to \sim 7h. It probably happened because of the radars' capability of monitoring the rain over the entire basin, which shows the importance of the acquired equipment and its proper operation.

4. CONCLUSION

As seen by the results presented above, despite the improvement of the monitoring net operated by the State Agency, there is still room for improvement. The scenarios assessed in this study show that the acquisition of more data does not necessary generate more accuracy to the system, which can be caused by the need of more sophisticate interpretation methodology.

On the other hand, the equipment made possible to increase the lead time more than twice, anticipating extreme events and the issuance of alerts to vulnerable neighborhoods. Such increased lead time provided more safety for the potentially affected population and the decrease of risks for human life and properties.

The next steps to be taken by the Agency should encompass data integration (radar, lightning, river levels and rain gauge) and hydrologic modeling of the watersheds using radar data and nowcast (Demerit et al., 2013). Both measures would help to reduce the false alarm rate and increase the lead time.
